Abstract

A supersymmetric see-saw model obeying the flavor symmetry $L_\mu - L_\tau$, which naturally predicts quasi-degenerate neutrinos, is investigated. Breaking of the symmetry is introduced in the Dirac mass matrix because it is the most economic choice in the sense that all interesting low and high energy phenomenology is made possible: we analyze the predictions for the low energy neutrino observables, for leptogenesis and for lepton flavor violating decays such as $\mu \rightarrow e\gamma$, where the SPS benchmark points for the SUSY parameters are used. It is outlined how these decays in connection with the requirement of successful leptogenesis and with correlations between the neutrino observables depend on the way the symmetry is broken.

1 Introduction

Explanation of the peculiar neutrino mass and mixing schemes is one of the most interesting tasks of particle physics. Motivated by spectacular experimental results, a very large number of models has been proposed in recent years [1]. Typically, the see-saw mechanism [2] is the starting point of most analyzes:

$$m_\nu = -m_D^T M_R^{-1} m_D , \quad (1)$$

where M_R is the mass matrix of three heavy Majorana neutrinos $N_{1,2,3}$ and m_D is a Dirac mass matrix resulting from the coupling of the Higgs doublet to the lepton doublets and the N_i . The light neutrino mass matrix m_ν is diagonalized by the PMNS matrix U defined via

$$U^T m_\nu U = \text{diag}(m_1, m_2, m_3) . \quad (2)$$

It can be parametrized as

$$U = \begin{pmatrix} c_{12} c_{13} & s_{12} c_{13} & s_{13} e^{-i\delta} \\ -c_{23} s_{12} - s_{23} s_{13} c_{12} e^{i\delta} & c_{23} c_{12} - s_{23} s_{13} s_{12} e^{i\delta} & s_{23} c_{13} \\ s_{23} s_{12} - c_{23} s_{13} c_{12} e^{i\delta} & -s_{23} c_{12} - c_{23} s_{13} s_{12} e^{i\delta} & c_{23} c_{13} \end{pmatrix} P , \quad (3)$$

where $P = \text{diag}(1, e^{i\alpha}, e^{i(\beta+\delta)})$ and c_{ij} , s_{ij} are defined as $\cos \theta_{ij}$ and $\sin \theta_{ij}$, respectively. By making assumptions for the unknown neutrino parameters (in particular the mass scale, ordering and phases), one can reconstruct m_ν with the help of our current knowledge of U and the mass differences [3]. Atmospheric neutrino mixing is close to maximal, $\theta_{23} \simeq \pi/4$, and corresponds to a large $\Delta m_A^2 = |m_3^2 - m_1^2| \simeq 2.5 \cdot 10^{-3} \text{ eV}^2$, whereas solar neutrino mixing is large but non-maximal, $\theta_{12} \simeq \pi/5$, and corresponds to a small $\Delta m_\odot^2 = m_2^2 - m_1^2 \simeq 8 \cdot 10^{-5} \text{ eV}^2$. The third mixing angle is known to be smaller than roughly $\pi/15$. Nothing is known about the mass scale, the mass ordering (sign of Δm_A^2) and the phases.

Several interesting hints towards the structure of m_ν can thereby be obtained, for instance the possibility of a μ - τ exchange symmetry [4, 5]. One other possible point of view is that a simple Abelian $U(1)$ symmetry is directly or effectively working on m_ν . Conservation of a flavor charge is implied by the conservation of this $U(1)$ and well-known cases are L_e [6] and $L_e - L_\mu - L_\tau$ [7], which lead to a normal ($m_3^2 \gg m_{1,2}^2$) and inverted ($m_2^2 \simeq m_1^2 \gg m_3^2$) mass hierarchy, respectively. Recently the case $L_\mu - L_\tau$ has been found to be also possible [5]. A low energy mass matrix conserving $L_\mu - L_\tau$ has the form

$$m_\nu = m_0 \begin{pmatrix} a & 0 & 0 \\ \cdot & 0 & b \\ \cdot & \cdot & 0 \end{pmatrix} \quad (4)$$

and for $a \simeq b$ one is lead to quasi-degenerate light neutrinos, i.e., masses $m_3 \simeq m_2 \simeq m_1 \equiv m_0 \lesssim \text{eV}$ much larger than the mass splittings. The neutrino mixing as predicted by the above matrix corresponds to $\theta_{13} = \theta_{12} = 0$ and $\theta_{23} = \pi/4$, which reflects the μ - τ symmetry

	$(\nu_e, e)_L$	$(\nu_\mu, \mu)_L$	$(\nu_\tau, \tau)_L$	N_1, e_R	N_2, μ_R	N_3, τ_R	Φ
$L_\mu - L_\tau$	0	1	-1	0	1	-1	0

Table 1: Particle content and charge under the $U(1)$ symmetry corresponding to $L_\mu - L_\tau$. Here Φ denotes the Higgs-doublet, which is responsible for the Dirac mass term.

inherent in a matrix conserving $L_\mu - L_\tau$. We remark here that L_e and $L_e - L_\mu - L_\tau$ do not possess μ - τ symmetry. Note further that besides $\theta_{12} = 0$ also $\Delta m_A^2 = 0$ holds. However, due to the quasi-degeneracy of the neutrinos, breaking of the symmetry with small parameters allows to easily overcome these shortcomings [5, 8, 9].

The flavor symmetry $L_\mu - L_\tau$ can be incorporated in a see-saw model [5]. The relevant Lagrangian reads

$$-\mathcal{L} = \bar{N}_i (m_D)_{i\alpha} (\nu_\alpha)_L + \frac{1}{2} \bar{N}_i (M_R)_{ij} N_j^c + h.c. \quad (5)$$

Here the superscript c denotes charge conjugation. The charge assignment of the particles under $L_\mu - L_\tau$ is given in Table 1. As a consequence, the charged lepton mass matrix is diagonal and in terms of mass matrices, we have (with $v_u = v \sin \beta$, $v = 174$ GeV, $\tan \beta$ the ratio of the up- and down-type Higgs doublets and M the high mass scale of the heavy singlets)

$$m_D = v_u \begin{pmatrix} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & d \end{pmatrix} \text{ and } M_R = M \begin{pmatrix} X & 0 & 0 \\ \cdot & 0 & Y \\ \cdot & \cdot & 0 \end{pmatrix}. \quad (6)$$

One eigenvalue of M_R has a mass MX and there is a Pseudo-Dirac pair with masses $\pm MY$. The low energy neutrino mass matrix is given by

$$m_\nu = -m_D^T M_R^{-1} m_D = -\frac{v_u^2}{M} \begin{pmatrix} \frac{a^2}{X} & 0 & 0 \\ \cdot & 0 & \frac{bd}{Y} \\ \cdot & \cdot & 0 \end{pmatrix}. \quad (7)$$

Note that the form of M_R corresponds to the form of m_ν from Eq. (4). The parameters a, b, d, X, Y are allowed by the symmetry and are therefore naturally of order one. As mentioned above, we need to break the symmetry in order to reproduce a non-zero atmospheric mass squared difference and a non-zero solar neutrino mixing angle. In addition, as we will see, successful leptogenesis and the existence of Lepton Flavor Violating (LFV) charged lepton decays such as $\mu \rightarrow e\gamma$ also require breaking terms. The possibilities to break the symmetry are numerous: we can

- break $L_\mu - L_\tau$ in the charged lepton sector. This will allow only the generation of $\theta_{12} \neq 0$ (note that large mixing has to be generated) and for LFV decays;
- break $L_\mu - L_\tau$ in M_R . This will allow only for $\theta_{12} \neq 0$, $\Delta m_A^2 \neq 0$ and for leptogenesis. Breaking in M_R has previously been analyzed in [5, 8, 9];
- break $L_\mu - L_\tau$ in m_D . This will allow for $\theta_{12} \neq 0$, $\Delta m_A^2 \neq 0$, for leptogenesis and for LFV decays.

We conclude that breaking $L_\mu - L_\tau$ in m_D is the most economic choice when one wants to generate all interesting observables. Of course, one would expect breaking in all possible sectors, but this will lead to little predictivity. For the sake of definiteness, we therefore consider only breaking in m_D .

In the following we will consider the case that the entries in M_R are complex and in m_D are real. The heavy neutrino mass matrix is

$$\frac{M_R}{M} = \begin{pmatrix} X e^{i\omega} & 0 & 0 \\ \cdot & 0 & Y e^{i\phi} \\ \cdot & \cdot & 0 \end{pmatrix} = V_R^* M_R^{\text{diag}} V_R^\dagger \equiv P_R \tilde{V}_R Q_R \begin{pmatrix} X & 0 & 0 \\ \cdot & Y & 0 \\ \cdot & \cdot & Y \end{pmatrix} Q_R \tilde{V}_R^T P_R, \quad (8)$$

where we have defined

$$\tilde{V}_R = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \\ 0 & -\sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \end{pmatrix}, \quad P_R = \begin{pmatrix} e^{i\omega/2} & 0 & 0 \\ 0 & e^{i\phi} & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad \text{and} \quad Q_R = \begin{pmatrix} 1 & 0 & 0 \\ 0 & i & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (9)$$

For real entries in M_R the matrix P_R is the unit matrix. When the breaking of $L_\mu - L_\tau$ takes place only in m_D we can quantify this as

$$m_D = v_u \begin{pmatrix} a & \epsilon_1 & \epsilon_2 \\ \eta_1 & b & \epsilon_3 \\ \eta_2 & \eta_3 & d \end{pmatrix}, \quad (10)$$

with $\epsilon_i, \eta_i \ll 1$. For symmetric m_D it would hold that $\epsilon_i = \eta_i$. With real entries in the Dirac mass matrix, there is only one physical phase, namely $\omega - \phi$. Consequently, low and high energy CP violation will be intimately related. We are therefore allowed to set ϕ to zero and keep only the phase ω . In the remaining part of this Section we will give the relevant expressions for the general form of m_D from Eq. (10), before considering more minimal braking scenarios in the next Section.

The parameters and the breaking are introduced at high scale. Consequently, radiative corrections, both below and in between the see-saw scales, can have impact on the results.

It has been shown in Ref. [8], however, that in the see-saw model basing on $L_\mu - L_\tau$ typically only θ_{12} gets corrected and that θ_{23} and $|U_{e3}|$, on which we later focus on, witness only little effects. Moreover, the textures of the mass matrices do only slightly change, i.e., small perturbations (over which we will scan numerically) remain small. We therefore neglect radiative effects, which should be a good approximation for our purposes.

In supersymmetric frameworks with universal boundary conditions there is an important possibility to probe the see-saw parameters, namely lepton flavor violating decays of charged leptons [10]. In the leading-log approximation one can obtain for the branching ratios of the decays $\mu \rightarrow e\gamma$, $\tau \rightarrow e\gamma$ and $\tau \rightarrow \mu\gamma$ the following formula [10]:

$$\text{B}(\ell_i \rightarrow \ell_j \gamma) \simeq \frac{\alpha_{\text{em}}^3}{G_F^2 m_S^8 v_u^4} \left| \frac{(3m_0^2 + A_0^2)}{8\pi^2} \right|^2 \left| \left(\tilde{m}_D^\dagger L \tilde{m}_D \right)_{ij} \right|^2 \tan^2 \beta, \quad (11)$$

where $\ell_i = e, \mu, \tau$ for $i = 1, 2, 3$. Here m_0 is the universal scalar mass, A_0 the universal trilinear coupling parameter, m_S represents a SUSY particle mass and $L = \ln \delta_{ij} M_i / M_X$, with M_i the heavy Majorana masses and $M_X = 2 \cdot 10^{16}$ GeV. The branching ratios have to be evaluated in the basis in which the heavy Majorana neutrinos are real and diagonal. To get into this basis we have to rotate m_D to obtain $\tilde{m}_D$. Having defined the diagonalization of M_R in Eq. (8) as $M_R = V_R^* M_R^{\text{diag}} V_R^\dagger$, then

$$m_D \rightarrow \tilde{m}_D = V_R^T m_D. \quad (12)$$

At 90% C.L., the current limit on the branching ratio of $B(\mu \rightarrow e\gamma)$ is $1.2 \cdot 10^{-11}$ [11] and future improvement by two orders of magnitude is expected [12]. In most of the relevant soft SUSY breaking parameter space, the expression $m_S^8 \simeq 0.5 m_0^2 m_{1/2}^2 (m_0^2 + 0.6 m_{1/2}^2)^2$, with $m_{1/2}$ being the universal gaugino mass, is an excellent approximation to the results obtained in a full renormalization group analysis [13]. Apparently, the branching ratios depend crucially on the SUSY masses. We choose here to use as examples the SPS benchmark points from Ref. [14] as given in Table 2.

Denoting $(3m_0^2 + A_0^2)^2 / m_S^8$ with $1/\tilde{m}_S^4$, we can write

$$\text{B}(\mu \rightarrow e\gamma) \simeq 1.2 \cdot 10^{-9} \left(\frac{200 \text{ GeV}}{\tilde{m}_S} \right)^4 \left| \left(\tilde{m}_D^\dagger L \tilde{m}_D \right)_{21} \right|^2 \frac{1}{v_u^4} \tan^2 \beta, \quad (13)$$

which has to be smaller than 10^{-11} . As we will see below, this can constrain the way $L_\mu - L_\tau$ should be broken.

It proves useful to consider also the double-ratios

$$\frac{\text{B}(\mu \rightarrow e + \gamma)}{\text{B}(\tau \rightarrow e + \gamma)} \simeq \frac{\left| (\tilde{m}_D^\dagger L \tilde{m}_D)_{21} \right|^2}{\left| (\tilde{m}_D^\dagger L \tilde{m}_D)_{31} \right|^2} \quad \text{and} \quad \frac{\text{B}(\mu \rightarrow e + \gamma)}{\text{B}(\tau \rightarrow \mu + \gamma)} \simeq \frac{\left| (\tilde{m}_D^\dagger L \tilde{m}_D)_{21} \right|^2}{\left| (\tilde{m}_D^\dagger L \tilde{m}_D)_{32} \right|^2}, \quad (14)$$

which are essentially independent on the SUSY parameters.

Point	m_0	$m_{1/2}$	A_0	$\tan \beta$
1a	100	250	-100	10
1b	200	400	0	30
2	1450	300	0	10
3	90	400	0	10
4	400	300	0	50
5	150	300	-1000	5

Table 2: SPS benchmark values for the mSUGRA parameters according to Ref. [14]. The values of m_0 , $m_{1/2}$ and A_0 are in GeV.

With the most general breaking structure in m_D given in Eq. (10) and with using $L_3 = L_2$, the off-diagonal entries of $\tilde{m}_D^\dagger L \tilde{m}_D$ read

$$\begin{aligned}
(\tilde{m}_D^\dagger L \tilde{m}_D)_{12} &= a \epsilon_1 L_1 + (b \eta_1 + \eta_2 \eta_3) L_2 \quad , \\
(\tilde{m}_D^\dagger L \tilde{m}_D)_{13} &= a \epsilon_2 L_1 + (d \eta_2 + \epsilon_3 \eta_1) L_2 \quad , \\
(\tilde{m}_D^\dagger L \tilde{m}_D)_{23} &= \epsilon_1 \epsilon_2 L_1 + (b \epsilon_3 + d \eta_3) L_2 \quad .
\end{aligned} \tag{15}$$

If $L_\mu - L_\tau$ would be broken only in the heavy neutrino sector (as in Refs. [5, 8, 9]), then $\tilde{m}_D^\dagger L \tilde{m}_D$ would be diagonal and the decays would be extremely suppressed. If we break $L_\mu - L_\tau$ only in the charged lepton sector, then $\tilde{m}_D = m_D U_\ell$, where U_ℓ diagonalizes the (now non-diagonal) charged lepton mass matrix. In this case $\tilde{m}_D^\dagger L \tilde{m}_D$ will have off-diagonal entries, but leptogenesis, to be discussed in the next paragraph, will not be possible.

Another very helpful and interesting aspect of see-saw models is the possibility to generate the baryon asymmetry of the Universe with the help of the leptogenesis mechanism [15]. In the case of thermal leptogenesis the baryon asymmetry is given by (for a review see, e.g., [16])

$$\eta_B = \frac{n_B}{n_\gamma} \simeq -1.04 \cdot 10^{-2} \kappa \varepsilon_1 \quad , \tag{16}$$

where ε_1 is the CP -violating asymmetry in the decay of the lightest right-handed Majorana neutrino N_1 having the mass M_1 , and κ is an efficiency factor calculated by solving the Boltzmann equations. A simple approximate expression for the efficiency factor κ in the case of thermal leptogenesis was given in [17]:

$$\frac{1}{\kappa} \simeq \frac{3.3 \cdot 10^{-3} \text{ eV}}{\tilde{m}_1} + \left(\frac{\tilde{m}_1}{0.55 \cdot 10^{-3} \text{ eV}} \right)^{1.16} \quad , \tag{17}$$

where the important parameter $\tilde{m}_1$ is given by

$$\tilde{m}_1 \equiv \frac{(\tilde{m}_D \tilde{m}_D^\dagger)_{11}}{M_1} \quad . \tag{18}$$

The CP -violating decay asymmetry ε_i has the form (with $x_j = M_j^2/M_i^2$):

$$\varepsilon_i = \frac{1}{8\pi} \frac{1}{v_u^2 (\tilde{m}_D \tilde{m}_D^\dagger)_{ii}} \sum_{j \neq i} \text{Im} \left\{ \left(\tilde{m}_D \tilde{m}_D^\dagger \right)_{ji}^2 \right\} \sqrt{x_j} \left(\frac{2}{1-x_j} - \ln \left(\frac{1+x_j}{x_j} \right) \right) . \quad (19)$$

For neutrinos close in mass the (self-energy) term proportional to $(1-x_j)^{-1}$ dominates [18]. It is important to note here that the Pseudo-Dirac pair of mass $Y M$ generates no decay asymmetry. The decay asymmetry is therefore generated by the decay of the neutrino with mass $M X$. It holds that $\tilde{m}_D \tilde{m}_D^\dagger = V_R^T m_D m_D^\dagger V_R^*$. In case of $X \sim Y$ we have¹

$$\varepsilon_X \simeq -\frac{1}{4\pi} \frac{1}{a^2 + \epsilon_1^2 + \epsilon_2^2} \frac{1}{Y/X - X/Y} 2(b\epsilon_1 + a\eta_1 + \epsilon_2\epsilon_3)(d\epsilon_2 + a\eta_2 + \epsilon_1\eta_3) \sin \omega \quad (20)$$

and

$$\tilde{m}_1 = \frac{v_u^2}{M} \frac{a^2 + \epsilon_1^2 + \epsilon_2^2}{X} . \quad (21)$$

Note that for no breaking of $L_\mu - L_\tau$ (i.e., $\eta_i = \epsilon_i = 0$) the decay asymmetry vanishes. In addition, if we break the symmetry only in the charged lepton sector we would have no decay asymmetry either, because $\tilde{m}_D \tilde{m}_D^\dagger$ would remain diagonal.

Numerically, η_B should be given by $6 \cdot 10^{-10}$ [19], where the small error is on the 5% level. The formalism described above has however several sources of uncertainty. First, recall that expression (17) holds only for hierarchical heavy neutrinos. The wash-out effect of the neutrinos with mass $\pm Y M$ is therefore not properly taken into account. Second, it has recently been realized [20] that flavor effects in leptogenesis can significantly affect the results. Taking these issues into account would require a thorough study and solution of the Boltzmann equations, which is surely beyond the scope of this letter. Instead, when we in the next Section calculate the baryon asymmetry for a specific breaking scenario, we consider the calculation as successful, when the result is $4 \cdot 10^{-10} \leq \eta_B \leq 8 \cdot 10^{-10}$, which is presumably still a very conservative range.

2 Breaking of $L_\mu - L_\tau$: Concrete Examples

Up to now we gave the relevant expressions for the Dirac mass matrix from Eq. (10), i.e., we used the most general breaking scenario. With six arbitrary breaking parameters in m_D , however, there is little predictive power in what regards the observables and in order to make interesting statements more simplification is needed. We therefore turn to minimal breaking scenarios in the sense of having as few parameters as possible. To constrain the possibilities even more, we require the presence of both low and high energy CP violation. If there is low energy CP violation in oscillation experiments can be checked most easily by

¹For extremely degenerate and therefore fine-tuned heavy neutrinos one should use a different formula [18].

calculating the following invariant [21], to which any CP violation in neutrino oscillations has to be proportional:

$$\text{Im} \{h_{12} h_{23} h_{31}\} = \Delta m_{21}^2 \Delta m_{31}^2 \Delta m_{32}^2 J_{CP} , \quad (22)$$

where $h = m_\nu^\dagger m_\nu$ and $J_{CP} = \frac{1}{8} \sin 2\theta_{12} \sin 2\theta_{23} \sin 2\theta_{13} \cos \theta_{13} \sin \delta$.

With only one perturbative parameter in m_D , this expression always vanishes. Hence, we should analyze scenarios with two non-zero perturbations in m_D , for which there are 15 possibilities. Except for one case, low energy mass matrices with one or two zeros are generated. Only one of them is ruled out by neutrino data, namely when the 23 and 32 elements of m_D are filled with non-zero entries. A low energy mass matrix with zeros in the 12 and 13 element would result, which can not reproduce the data [22]. More cases can be ruled out when we require the presence high energy CP violation, i.e., leptogenesis. Recall that the decay asymmetry is proportional to $(b\epsilon_1 + a\eta_1 + \epsilon_2\epsilon_3)(d\epsilon_2 + a\eta_2 + \epsilon_1\eta_3)$. Asking this expression to be non-zero rules out 8 more cases, leaving us with 6 remaining ones. In what regards the results of the breaking scenarios, we are interested in particular in the branching ratios of the LFV decays, some of which will be forbidden by certain scenarios. We have summarized in Table 3 all 15 possibilities together with their predictions for the branching ratios of the LFV processes, for low energy CP violation, for η_B , and with a correlation for the oscillation parameters as obtained in [22, 23]. All obtained cases with two zeros are only possible for quasi-degenerate neutrinos [22]. Cases with one zero entry are in general possible also for other allowed mass hierarchies [23], but here we focus only on quasi-degenerate neutrinos. The one-zero matrices always come together with zero η_B and are disregarded anyway. From the six cases allowing for a non-zero baryon asymmetry one case has no correlation for the low energy observables and all branching ratios are non-zero. Four cases generating two zeros in the low energy mass matrix have indistinguishable neutrino phenomenology, but differ in the predictions for the branching ratios, except for 2 cases which predict identical results. From the six matrices allowing for leptogenesis, five also predict the decay $\mu \rightarrow e\gamma$. We would like to remark here that some of the 15 possibilities have the amusing feature that *there is low energy CP violation but no leptogenesis*. There are no cases in which it is the other way around. Note finally that the rate for neutrinoless double beta decay (which is proportional to the ee element of m_ν) is always non-zero.

Let us discuss one example in detail, namely the following form of m_D and the resulting low energy mass matrix m_ν :

$$m_D = v_u \begin{pmatrix} a & \epsilon_1 & 0 \\ 0 & b & 0 \\ 0 & \eta_3 & d \end{pmatrix} \Rightarrow m_\nu = -e^{-i\omega} \frac{v_u^2}{M} \begin{pmatrix} \frac{a^2}{X} & \frac{a\epsilon_1}{X} & 0 \\ \cdot & \frac{\epsilon_1^2}{X} + 2\frac{b\eta_3}{Y} e^{i\omega} & \frac{bd}{Y} e^{i\omega} \\ \cdot & \cdot & 0 \end{pmatrix} . \quad (23)$$

The ee and the $\mu\tau$ elements are allowed by $L_\mu - L_\tau$ and, as it should, the additional non-zero entries are suppressed by the small breaking parameters. The expressions relevant for

high and low energy CP violation are

$$\begin{aligned}\varepsilon_X &\simeq -\frac{1}{2\pi} \frac{1}{Y/X - X/Y} \frac{b}{a^2} \epsilon_1^2 \eta_3 \sin \omega \quad \text{and} \\ \text{Im} \{h_{12} h_{23} h_{31}\} &= \left(\frac{v_u^2}{M}\right)^6 2 \frac{a^4 b^3 d^2}{X^3 Y^3} \epsilon_1^2 \eta_3 \sin \omega .\end{aligned}\tag{24}$$

The decay $\tau \rightarrow e\gamma$ is forbidden, whereas the branching ratio for $\mu \rightarrow e\gamma$ ($\tau \rightarrow \mu\gamma$) is proportional to $|a \epsilon_1 L_1|^2 (|d \eta_3 L_2|^2)$. In what regards these LFV decays, let us return to Eqs. (13) and (15). Given the fact that a is of order one, it is apparent that $|(\tilde{m}_D^\dagger L \tilde{m}_D)_{12}|^2/v_u^4$ is of the order of $\epsilon_1^2 L_1^2 \sim 10 \epsilon_1^2$. From Eq. (13) we see that for typical values of $\tilde{m}_S \simeq 200$ GeV and $\tan^2 \beta \simeq 10^2$, the branching ratio for $\mu \rightarrow e\gamma$ is roughly given by $10^{-6} \epsilon_1^2$. This indicates small values of ϵ_1 , which however also decreases the decay asymmetry parameter ε_1 , which is relevant for leptogenesis. With this crude estimate we can see that the requirement of successful leptogenesis makes the branching ratio of $\mu \rightarrow e\gamma$ in general rather large, thereby snookering such scenarios. In principle one could let the heavy neutrino masses be extremely degenerate, so that the decay asymmetry is large even for small perturbative parameters, but this is regarded as fine-tuning. The underlying reason for the potentially too large branching ratios (for more model-independent analyzes, see for instance [24]) is that the entries allowed by the symmetry in m_D are all of order one. It is therefore a generic issue of the framework.

We next perform a numerical search for successful parameters a, b, d, X, Y (which are required to be of order one) and for the two perturbative parameters (which are required to be at least one order of magnitude smaller). The neutrino oscillation observables are required to lie within their 3σ ranges from Ref. [3]. We also demand $1 - X/Y \geq 0.1$ so that the heavy neutrinos are not too close in mass, i.e., Eq. (19) can still be used. We checked that the corrections to Eq. (19) are indeed subleading in this case. The upper left plot in Fig. 1 shows $B(\mu \rightarrow e\gamma)$ against η_B for the SPS benchmark points 1a, 2 and 5. It turns out that points 1a and 1b generate practically identical results, and also points 2 and 3 are indistinguishable. The results for point 4 lie between points 2 and 5. The correlation between η_B and $B(\mu \rightarrow e\gamma)$ is rather strong because both ε_X and the branching ratio are proportional to ϵ_1^2 . The upper right plot shows the ratio of the two non-zero branching ratios, which is below one for successful leptogenesis. We included the current and a future bound on the branching ratio and also indicated how many points lie in the range $4 \cdot 10^{-10} \leq \eta_B \leq 8 \cdot 10^{-10}$. Except for the SPS point 2, which includes TeV scale parameters, $B(\mu \rightarrow e\gamma)$ is typically too large². As mentioned before, reducing the order of magnitude of the small perturbative parameters will strongly reduce η_B . A way to evade this problem is either to assume the SUSY parameters to be very large or to assume a breaking scheme of $L_\mu - L_\tau$ with zero $B(\mu \rightarrow e\gamma)$.

²We remark that point 5 leads to a too small Higgs mass anyway [25].

Such an example is³

$$m_D = v_u \begin{pmatrix} a & 0 & \epsilon_2 \\ 0 & b & \epsilon_3 \\ 0 & 0 & d \end{pmatrix} \Rightarrow m_\nu = -e^{-i\omega} \frac{v_u^2}{M} \begin{pmatrix} \frac{a^2}{X} & 0 & \frac{a\epsilon_2}{X} \\ \cdot & 0 & \frac{bd}{Y} e^{i\omega} \\ \cdot & \cdot & \frac{\epsilon_2^2}{X} + 2\frac{d\epsilon_3}{Y} e^{i\omega} \end{pmatrix}. \quad (25)$$

This example has no decay $\mu \rightarrow e\gamma$, and the branching ratio for $\tau \rightarrow e\gamma$ ($\tau \rightarrow \mu\gamma$) is proportional to $|a\epsilon_2 L_1|^2$ ($|b\epsilon_3 L_2|^2$). CP violation is governed by

$$\begin{aligned} \varepsilon_X &\simeq -\frac{1}{2\pi} \frac{1}{Y/X - X/Y} \frac{d}{a^2} \epsilon_2^2 \epsilon_3 \sin \omega \quad \text{and} \\ \text{Im} \{h_{12} h_{23} h_{31}\} &= -\left(\frac{v_u^2}{M}\right)^6 2 \frac{a^4 d^3 b^2}{X^3 Y^3} \epsilon_2^2 \epsilon_3 \sin \omega. \end{aligned} \quad (26)$$

The lower left plot of Fig. 1 shows $B(\tau \rightarrow \mu\gamma)$ against η_B . We included the current ($6.8 \cdot 10^{-8}$ [26]) and a future bound ($5 \cdot 10^{-9}$, see [25]) on the branching ratio and also indicated how many points lie in the range $4 \cdot 10^{-10} \leq \eta_B \leq 8 \cdot 10^{-10}$. We see that $\tau \rightarrow \mu\gamma$ lies in an observable range unless the SUSY masses are in the TeV range. The correlation between η_B and the branching ratio is weaker than in the previous example, because $\varepsilon_X \propto \epsilon_3$ but $B(\tau \rightarrow \mu\gamma) \propto \epsilon_3^2$. The lower right plot shows the ratio of the two non-zero branching ratios, which is above one.

It is of course possible to diagonalize the mass matrices Eqs. (23, 25) and express the observables in terms of the parameters appearing in m_D and M_R , but the resulting expressions are rather cumbersome and little insight is gained. We rather note that from the condition that the $e\tau$ and $\tau\tau$ entries (or the $e\mu$ and $\mu\mu$) vanish, one can obtain [22]

$$||U_{e3}| \cos \delta \tan 2\theta_{23}| \simeq \frac{\Delta m_\odot^2}{2\Delta m_A^2} \sin 2\theta_{12}. \quad (27)$$

Since $\Delta m_\odot^2 / \Delta m_A^2 \ll 1$, this expression means that θ_{23} can not be exactly maximal: $\sin^2 \theta_{23} \neq \frac{1}{2}$. Moreover, if $|U_{e3}|$ is sizable then $\cos \delta$ must be small, and therefore large CP violation is expected in this case: $J_{CP} \simeq |U_{e3}|/4$. These features are nicely illustrated in Fig. 2, where we have plotted $|U_{e3}|$ against J_{CP} and against $\sin^2 \theta_{23}$. Atmospheric neutrino mixing can not be exactly maximal and if $|U_{e3}|$ is large, CP violation is also large. Identical results occur for Eq. (23). Another interplay of variables occurs when θ_{23} is close to maximal. This implies again from Eq. (27) that $\cos \delta$ is small and J_{CP} is large. Large J_{CP} , in turn, implies from Eq. (26) that the decay asymmetry is large, because both ε_X and J_{CP} are proportional to $\sin \omega$. Hence, the closer θ_{23} is to $\pi/4$, the smaller becomes η_B . This is illustrated in Fig. 3. We indicated the values $\sin^2 \theta_{23} = 0.45$ and 0.55 , which are the approximate lower and upper limits in order to still have successful leptogenesis.

We stress here that both examples, Eqs. (23, 25), predict basically identical neutrino phenomenology, but differ dramatically in their predictions for the LFV decays.

³The remaining three cases with interesting correlations of the neutrino observables are found to be very fine-tuned, i.e., the numerical search for successful parameter values hardly finds any points.

3 Summary and Conclusions

A supersymmetric see-saw model obeying the flavor symmetry $L_\mu - L_\tau$ was analyzed. In the low energy sector this generates quasi-degenerate neutrinos, vanishing θ_{13} and maximal atmospheric neutrino mixing. With strict conservation of the symmetry both leptogenesis and LFV are not possible and in addition θ_{12} and the atmospheric Δm^2 is zero. Possibilities to break $L_\mu - L_\tau$ were considered and it was found that the most economic possibility is to include breaking only in m_D . Two small breaking parameters are required in order to allow for low energy CP violation. Generation of the baryon asymmetry via leptogenesis is possible with heavy neutrino masses of similar size. We discussed how the breaking of the symmetry reflects in low energy observables, and in particular in the predictions for the LFV decays $\mu \rightarrow e\gamma$, $\tau \rightarrow e\gamma$ and $\tau \rightarrow \mu\gamma$. Scenarios with indistinguishable neutrino phenomenology can lead to drastically different relations between the branching ratios.
